1 Abstract

Authors: Manuel Moser, Yannick Suter, Raffael Theiler

Title: Pedestrian dynamics in long, narrow hallways

In this project, we want to have a closer look at pedestrians in narrow hallways, motivated by a situation at Zurich main station. To do this, we simulate pedestrians with Matlab who walk according to some rules. We managed our agents to pass each other by, to look ahead a few meters and to decide where to walk next.

At first, we wanted to have a closer look at the pedestrian flux when the number of persons per minute entering is increased, when there are clearly more people moving in the same direction against a few in the other direction. Next, we wanted to analyze the influence of aggressive fast people in a rush, slowly moving obstacles and the influence of drunkard (randomized walking) on the pedestrian flux.

But soon, our attention turned more to building/creating everything on our own and less about a fast simulation of different situations.

The main outcome of our simulations was that pedestrians tend to get stuck or create jams as soon as there are lots of people trying to pass the same hallway. The exact same hallway can work smoothly if there are not too many people, but jams can arise quickly. And once a jam starts, it often spreads out because people have to stop and walk slower.

Finally, we arrived at the following conclusions: To improve the pedestrian flux, broadening a hallway is a superb solution. Therefore, at our situation scene at Zurich main station, it would be best if the hall users would try to leave more space for the pedestrians, and if the food shops Imagine and Nordsee wouldn't have chairs and tables outside.

2 Individual contributions

Manuel: report, revising & commenting
Yannick: logical functions, revising & debugging
Raffael: graphical functions, visualization & agents

Listed above are only the main tasks everyone of us took care of, but we shared most of the work. The github commit report is not always mirroring the work behind those uploads because we often worked together on the code, debugged, commented and worked on the documentation while swapping laptops.

3 Introduction and Motivation

3.1 Motivation

As many commuters too, we all got annoyed by people rushing through the small corridor left in the Zurich main station hall (the path between burger king and groups meeting point) during the Oktoberfest, market days, concerts and other occasions when going from the platform in direction towards the Central and further on. So when thinking about a simulation project, this quickly crossed our minds. Special about this situation of a narrow but long corridor is that there's not much space to avoid other pedestrians to the side, especially if there are lots of other people whereas there is no need of path optimisation as the ultimate goal is to cross the hallway without crashing into someone else.

Being sometimes in such a situation inside that small corridor, we observed a very special dynamic between people rushing by, people just slendering about, people who want to talk to each other and so on.

3.2 Fundamental Questions

The fundamental questions of our simulation project we started with were:

- We try to simulate the pedestrian flux of agents in a hallway in the following different situations: Rush hour (danger of jamming), much more agents in one direction than in the other, with an static obstacle (if possible), with aggressive/very fast or slow agents, random path agent (drunkard). Will the pedestrian flux run smoothly or will they block each other and be stuck?
- Will the implementation of a rudimentary kind of thinking/looking ahead help to avoid blockages? If possible, we may determine the limits for which the goal of passing is achieved with and without this implementation and compare them.
- Will there be group dynamics or similar behaviours of agents even if they're only programmed to walk to the other side, each on his own?

As soon as the programming phase started, we realized there was a major point of importance about this work we all were aware of, but had forgot to think about beforehand. We did not want to start with a simulation already created, but build something "new". So we started off creating our logic functions that would allow the agents to avoid crashing into other agents. As a consequence new fundamental questions arised:

- Starting with the idea of looking ahead, how can we turn this into a rudimentary kind of intelligence?

- How can we have a look at the main station situation but keep our agents as random as possible?
- Using our own kind of rudimentary intelligence, will a form of collective behaviour follow? Will we be able to remodel the dynamics that follow if people start to rush forward while other are considerable slower?

3.3 Expected Results

We thought that there would be lots of changes in the direction of walking to the left and right while trying to avoid other agents. With rising amount of agents we expected more jams, although this seems obvious. We thought that in our simulation we would have to deal with massive jams because the agents were not communicating with each other in any way. Our implementation of "looking ahead" as a form of intelligence would probably improve the people flux but only to a limited range. The formation of columns of people as a way to avoid the zig-zagging of the agents might appear.

4 Description of the Model

4.1 General considerations

As we wanted to describe a situation with people, we chose a model based on discrete agents. They should be able to walk freely along their path until they hit an obstacle, in which case they should be able to determine a way to avoid the obstacle. Obstacles could be walls, objects placed in the path or simply other agents. The main goal of any agent is to get to the other side of the path as quickly as possible, if possible without crashing into other things. As the global situation changes with each "step" an agents does and also with the appearance of new agents, a step-by-step iteration was chosen to propagate the situation in time in which the the optimal direction is calculated all the time. The other approach of calculating a certain path from start to finish was rejected as it probably cannot be done for the uncertainties mentioned above, namely the random appearance of new agents which could block the calculated path. Also, this is not a main point for our situation because there's not a specific destination an agent walks to, but a intended zone to go to. In a hallway without exits on the sides, the goal only is to traverse it.

Any agent's goal is to get to the other side as quickly as possible, although our model cannot accommodate the requirement of the quickest possible path. Because of the step-by-step iteration, any situation is repeatedly analyzed and (hopefully) the best way to proceed is chosen. As this is only a short time period and we only consider an agent's situation in a local environment, it cannot guarantee to give the best outcome overall. To make a long story short, we used a *local search algorithm* combined with a greedy algorithm for each agent.

4.2 Walls and other static obstacles

If a narrow hallway should be a narrow hallway, it needs two walls. Although this statement is obvious, it can be implemented in various ways. We chose to use static agents with a small radius to act as a wall, as it allows the creation of many different hallways. They can also be used as static objects representing obstacles like chairs and tables which could stand in the path an agent has to follow to get to the other side. For our simulation, this was a very flexible way which also allows a quick adaption to other situations if necessary.

4.3 Agents

The basis of the simulation is the agent. An agent should represent a person in real life. We assumed that the hallway was not a place to linger about, therefore they

should try to get to the other side as quickly as possible. In order to do so, they need to be aware of all the things around them that they might bump into. This was the origin of the thought that any agents only looks forward as the obstacles will be in the path before them. In our model, they also need some intelligence to get around an obstacle and avoid running into other agents. To do so, the agent should consider all things within a circle of defined radius in front of him while everything else doesn't bother him. Again, this tries to get a local solution to our problem in the hope that the overall solution is still a good one. As one usually doesn't walk backwards, our agents only walk forwards. This might not be true for all situations but for most of the situations a pedestrian walks into, and it simplifies the model considerably. We also think that, if a pedestrian does only walk more or less forwards and won't be involved in a jam or collision, his passing time will be quite good compared a perfect chosen path, if a such path even exists.

In comparison to previous models which used a force field to guide the agents, we thought that this approach is more realistic as the force field approach given that the force field already defines the optimal solution one is looking for. It should also prove to be more adaptable within a reasonable time frame to other problems.

4.4 Intelligence

4.4.1 General considerations regarding the necessary intelligence

For the model to work properly, a sensible solution to deal with the problem of finding the right path must be found. We do not claim to have found the best solution but believe our model to be a fairly good solution.

The presence of every other agent, be it agent or wall, inside a semi-circle in front of the currently considered agent clearly must have an influence in order not to bump into it. The fundamental idea is to get a function for every agent inside this agent's semi-circle which reproduces the effect it has on the path the considered agent would take without them being in his semi-circle. All of these functions will then be added and the maximum value would be taken as the best way to go forward. An additional function is added which should represent the tendency to go straight forward.

All functions were calculated as functions of x . This x is connected to an angle φ given by $\arctan(x)$. A value of $\varphi = -\pi/2$ would correspond to walking sideways to the left, $\varphi = 0$ to walk straight forward and $\varphi = \pi/2$ to walking sideways to the right, always viewed in the direction the agent wants to go.

A function calculated in x will then be superimposed on φ which corresponds to a mapping of the function onto a polar grid. A possible disadvantage of this procedure

is that φ does not range from $-\pi/2$ to $\pi/2$ and therefore doesn't reach the full semi-circle as x is bounded and doesn't reach infinity. We consider this to be negligible as for reasonably high values of x , φ gets close to $\pm\pi/2$ and it is rarely in the interest of an agent to walk purely sideways.

We chose this way as it seemed easier and more intuitive to handle x -values for many different situations. It allowed an easier and (hopefully) more understandable way to the functions used to model various influences.

For an agent coming from the other side, we used a function of the type

$$y(x) = \frac{1}{(|x - x_{\text{Agent}}|)^n} \quad (1)$$

and set the y values corresponding to x values on a collision course to zero. The exact implementation will be treated in chapter *Implementation* where equation (1) is modified to accommodate for various different parameters. If an agent has another agent in front of him which is walking in the same direction but slower, the function given in (1) is also applied to overtake the slower agent.

Should another agent walk in the same direction, but with higher speed, we thought that it would be logical to follow him. This was done using a Gaussian curve centered on the direction of the faster agent.

Agents moving in the same direction with the same speed have no influence on each other in our model. Two agents standing still on the other hand will also be handled using the function given in (1) to avoid standoffs.

4.4.2 Necessary parameters and variables

We reckon that the important parameters necessary to assess the influence of one agent onto the other agents are

- α_X , the angle between the centers of the two agents with respect to the y-axis
- Δv , the difference in velocity, set to be negative for this situation
- β_{Links} and β_{Rechts} , two angles describing which directions of the path to be chosen would lead to a collision.
- $r_S = r_1 + r_2$ being the sum of the two involved agent's radii
- d , the distance between the two involved agents

In figure 3 (given in the implementation chapter) a graphical depiction of α_X , β_{Links} and β_{Rechts} is given alongside the way to calculate them.

The sign of Δv was chosen to be positive in the case of two agents walking in the same direction and negative in the case of crossing agents.

4.4.3 Collision detection and the its connection to the iteration speed

Collision detection has to be carried out in order to keep the simulation physically possible. We used an approach in which the vector describing the path the agent walks on is subdivided into several small steps. The agent then goes on as far as he can. To avoid the agents sticking too close together and therefore not being able to move anymore, the number of subdivisions should be rather small.

Given that the length of the vector is determined by the iteration time intervall Δt , it is also important for Δt to be not too small. This has a physiscal representation as in reality one goes on in discrete steps, not infinitesimally small steps that one would get in the case of $\Delta t \rightarrow 0$.

4.5 Discretization

As it is a numerical calculation, at some point there has to be a numerical discretization. Since we wanted the agents to be able to move around freely, we abandoned the idea of using a grid on which the agents could walk around in favour of a continuous space simulation. The discretization comes about in the form of the functions and angles to be calculated.

4.6 Spawning of new agents

A hallway usually has at its two endings a more open space than the hallway where the flow of people arriving from the hallway will disperse. In order for things not to get too messy, we decided that agents would simply cease to exist if they reach a line (called dstruction line) which would signify the beginning of this region of dispersion. Newly spawned agents would be created on a line (called spawn line) below the destruction line and pass a short distance without oncoming agents so that they could already orientate themselves according to the flow of agents walking the other way. This could be important in cases where the agents would form columns and newly spawned agents could adapt to that by not interrupting the column.

5 Implementation

5.1 General considerations

5.1.1 Introduction

We had to build our implementation around several different desires:

- The code has to be expandable with additional features.
- If there is a class model it has to be simple because the project is not that big.
- Constants should be easy to find and adjust.

According to those points the simulation code is a mixture between classes and cascaded functions. At the top is a file defining all the global constants, *defineConstants.m*. This approach is maybe not very correct in terms of a good programming style but it makes it very simple to adjust smaller details and to keep an overview over all the constants necessary to make the model work and to specify the field the agents shall walk in. It also provides an easy way to store and therefore document each run by simply saving the file containing all constants to a textfile. All constants and variables are considered to be in SI-Units, if not mentioned otherwise. This means that all position specifications are given in meters, the velocity in meters per second and so on.

There are 3 classes implemented: *simulation.m*, *agent.m* and *drawing.m*. The further description about these classes can be found in the table or direct in the header of the class files. The rest of the code is split up into different logical functions.

Class	Description	Parent
simulation.m	This class offers all the functions for simulations. It can be executed with different parameters depending on the users preferences.	Matlab "handle" class
agent.m	This class is a container for all the agent data such as its radius and the coordinates.	Matlab "handle" class
drawing.m	This class can draw a field containing agents.	Matlab "handle" class

The class diagram given in figure 1 is a summary of the most important functions and properties in this project.

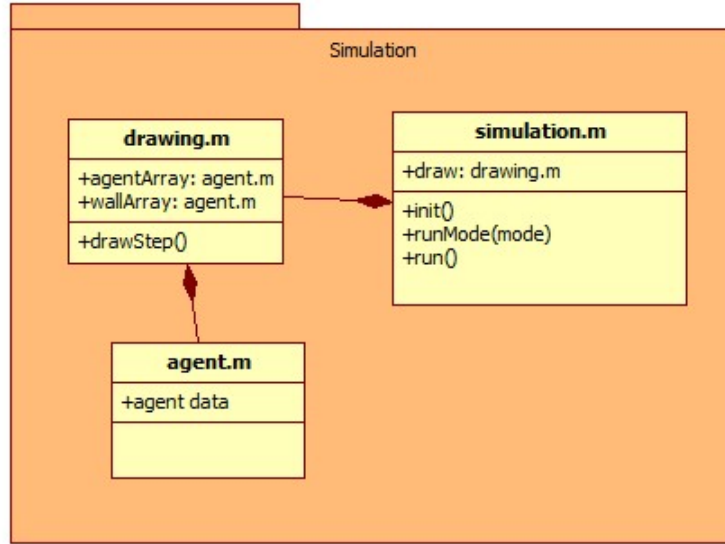

Figure 1: Class diagram of our model. From bottom to top we implemented a class *agent.m*, *drawing.m* and *simulation.m*.

5.1.2 Important classes to run the simulation

The simulation class *simulation.m* describes an object that wraps all the different possibilities of our simulation program. It's the start point for a new simulation, runs this simulation and collects all the data requested from the agents and the simulated environment. The drawing class *drawing.m* handles all graphical aspects of our simulation. The agent class *agent.m* has a subchapter of its own because it fulfills a very different role than the two classes mentioned previously.

The main flow of a run cycle is described in the activity diagram given in figure 2.

Important properties of the simulation class *simulation.m* are:

- **DRAW:** The *drawing.m* implementation.
- **RESULT:** A matrix containing simulation results.
- **ADDITIONALRESULT:** A matrix containing further simulation results.
- **EVALUATE TIME:** A vector used to evaluate the time an agent has spent in the simulation during its existence.

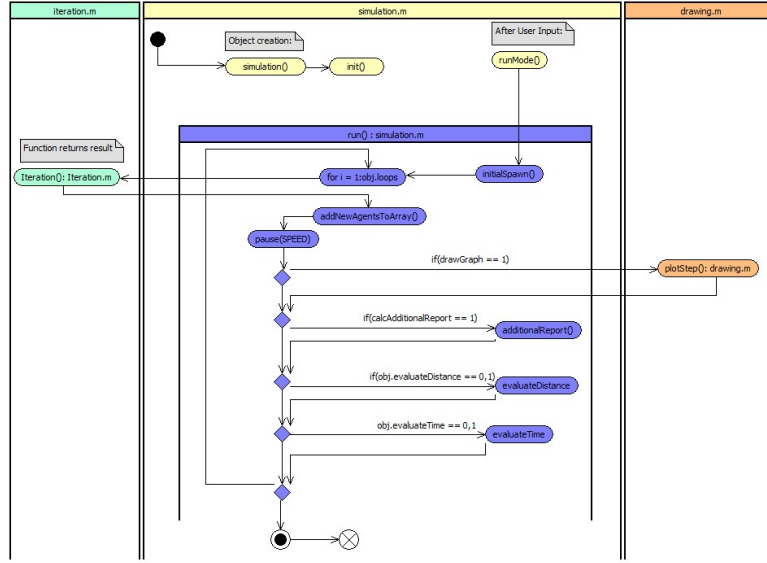

Figure 2: Activity diagram of our model.

- **EVALUATEDISTANCE**: A vector used to evaluate the distance an agent has covered in the simulation during its existence.

All methods of the simulation class are listed here:

- **SIMULATION()**: Constructor, sets up the object.
- **INIT()**: Initializes the existing object: Fills up arrays with empty objects, sets up vectors, etc.
- **RUNMODE()**: Pass console like parameters to this function to run a simulation and choose between various runmodes.
- **ADDITIONALREPORT()**: Fills the additionalResult matrix with data.
- **CALCPOSSIBLEAGENTS()**: Calculates the maximum possible number of agents for the set area.
- **RANDPREFIX()**: Randomly generates 1 or -1 to set the spawnpoint (top or bottom).
- **INITIALSPAWN()**: Fills up the agent array with new *agent.m* objects. They have priority 0 which corresponds to non-existing agents.

- `ADDNEWAGENTS TOARRAY()`: Used to add new agents to the simulation while running.
- `BALANCEPROBABILITY()`: Balances the probabilities to spawn agents.
- `RUN()`: Main function to run a simulation after everything is set up and ready.

See also the activity diagram (figure 2) for a better overview on how these method functions are used in the simulation.

The drawing class *drawing.m* basically adapts simple Matlab drawing functions and converts them into useful functions for this project. As a result it's very easy to draw the new situation after a simulation step by simply calling the method `PLOTSTEP()`.

5.1.3 Properties

Important properties:

- `PARTICLE DENSITY`: Resolution for wall *agent.m* objects in $\frac{\text{agents}}{\text{meter}}$.
- `WIDTH`: The field width.
- `LENGTH`: The field length.
- `WALLARRAY`: All the agent.m object for the wall.
- `AGENTARRAY`: All the agent.m objects for the simulation.

5.1.4 Methods

All methods are listed here:

- `DRAWING()`: Constructor, sets up the object.
- `CREATEWALL()`: Creates wall agents according to the settings.
- `PLOTSTEP()`: Main function, plots all the agents on a field with the walls and the starting lines.
- `DRAWWALLSQUARES`: Draws the walls on the side.
- `CIRCLEPLOT`: Draws circles for the agents.
- `DRAWLINE`: Draws a line with coordinates. Used for the direction indicators etc.

How the field is created is the subject of subchapter 5.4.

5.1.5 Simplifications

Some simplifications and constraints on the model had to be introduced during the implementation to keep the whole simulation manageable. At first we decided that the agents should walk either up or down and used the sign of an agent's velocity as an indication in which direction the agent goes. In the logic functions, a discretization had to be introduced for the numerical evaluations of functions. To interconvert values between different vectors, the function *closest.m* was used.

As a consequence of the model used for the logic functions, the agents will only be able to look forward. Because of the actual way *logicFunction.m* was implemented (see subchapter 5.5), they would not use the full $\pm 90^\circ$ in front and on the side of them. We thought this not to be too critical as the human visual field is also smaller than 180° , if one doesn't move the head.

If one walks through the main station, it is visible that many people are not on their own. Groups tend to walk together as they want to chat. This can be seen very clearly in couples which try to walk side-by-side. To incorporate this in our model, we would have to introduce some kind of coupling between agents, for example that they would always be below a certain distance from each other. As we constructed our model from scratch, we thought it should be challenging enough to make it work with completely independent agents.

The hallway in the main station in Zurich is approximately 60 meters long. We shortened the way to 30 meters as we reckon that the same affects should be visible over that length. This saves some time for the simulations as the way until the agents from the opposite directions meet is considerably shortened.

5.2 How to run a simulation

To start a simulation, simply change to the `"/code"` directory in your local matlab installation. Then type `"run"` into the command window. This will set up a new simulation environment. This environment can be accessed through the `"sim"` variable.

The run script will ask for a `"runmode"` and if you like to save the data. Supported runmodes are:

normal	normal mode with many wall agents
fasttest	faster mode with lesser wall agents

Supported parameters are:

-nograph	simulation draws no graph, can be used if graphical output is not necessary.
-report	additional report will be recorded
-nodirections	removes the direction markers on top of the agents.

A string could be for example: "normal -nograph -report". For a more detailed example please view the header of the run.m file.

If one wants to save the data, type "Y" as one is asked whether the data shall be saved and type in the name to the location on the computer where the data shall be stored. As a default, they are saved into the sim folder. Then the *defineConstants.m* file containing all the constants is saved as a .txt file with the runmode appended. After the simulation is finished, the workspace variables containing the "sim" variable are saved as a .mat file. The situation after the last iteration is drawn and saved as a png, also when the parameter -nograph was called. This allows a first visual check on how a run went.

5.3 Agents

As the model is agent-based, we wanted to implement them as such. Therefore we created a class called agent.m. Every agent has the following properties which are critical for the simulation:

- Radius of the agent called RADIUS
- An x coordinate called CORDX
- A y coordinate called CORDY
- A maximal velocity called MAXSPEED
- An actual velocity called ACTSPEED
- A priority called PRIORITY

Two more properties were introduced later for the analysis of the model. They are called DISTANCE and TIME and are used to monitor the time and pathlength an agent needs for crossing the field. The property ANGLE stores the angle an agent wants to walk. This was used to show the way they want to walk to during the simulation.

A circle is the mathematically easiest shape to consider especially for collision detections which have to be done later all the time. In addition, we consider the circle

to be a good approximation as one also needs some space to move as the legs cover some space in front and behind the body. A circle is also practical as it only needs one parameter entirely for the shape which is the radius. Using this approach, every agent can have a different radius.

The coordinates of the agent with respect to a cartesian grid centered at the lower left of the whole field are vital for all calculations. They are also needed to define the circle representing the agent in the plane. After each iteration, they will be adjusted to the new situation.

Every agent has a maximum velocity. The actual velocity of an agent gives its actual speed. If there is no obstacle, it will be the maximum velocity. In the initialization of an agent, the first actual velocity is set to be equal to the maximum velocity. As velocity is in principle a vectorial quantity, we used the sign of the maximum velocity to determine the way an agent walks. By our own convention a positive sign means to go upwards and a negative sign to go downwards.

Every agent has a priority and usually a random number between 0 and 1. It is used to determine the order in which the agents move through one iteration step. A high priority means that the agent will walk first. A high priority value can be attributed to an agent which will always try to push his way through.

The priority is also used to mark inactive agents. As all arrays are stored in an array of class agent, a priority of 0 denotes an empty position and will not be drawn and are considered. Any new agent is placed at the first position in the array of agents with a priority of 0. If an agent reaches its goal, it can be deleted by setting the priority to zero. This is the only time the priority value is changed after the creation of an agent.

The class agent was implemented using *handle* in the class definition. This has the same effect as *call by reference* in C++ as there is after the creation only one instance of the agent, specially in the case where it is passed down to functions. A change of the value inside the function will be effective also outside the function which saves the step of giving the whole array of agents back after every function call which changes the coordinates or the actual velocity.

5.4 Drawing of the field

To draw the field, the matlab API is used in a very basic way. Matlab supports the drawing of different shapes like circles, squares and lines. They can be combined in a single plot to create more complex graphic objects. The field is repainted after every simulation step by different functions. There is a separate function for the wall

painting and to paint the spawn-lines on both sides. The agents are painted in two steps. First it paints a round "rectangle" to create a cyclic shape and then, if the user desires, direction indicators on top of it. All the drawing functions are processed in a procedural manner. Every agent is handled individually.

The field is defined by its wall agents. They could be in any shape. For example, if one wants extend the field with an obstacle somewhere between the spawn lines it can be defined by adding wall-agents to the specific coordinates. The easiest way to do so is to modify the `createWall()` function (which currently creates wall-agents on the left and the right side to simulate a passage). Keep in mind that the coordinate systems zero point is on the lower left side. All wall agents are currently invisible.

If one does extend the field with other obstacles or different shaped walls and if its not possible to frame the new situation with a simple geometric structure, the wall agents have to be drawn again. This is currently disabled because it slows down the simulation speed and the straight walls can be easily substituted with a long small rectangle. Drawing wall-agents is very simple due to the fact that they are exactly the same object type like a normal, moving agent. One can combine the two arrays (wall-agents and the moving agents) and let it draw by the iteration loop.

Currently walls are coloured black, agents moving from top to bottom are painted in blue and those from bottom to top are red. The agents direction indicators are painted black. All the distances are in meters.

5.5 Logical functions

5.5.1 General considerations

The heart of the simulation is the function *logicFunction.m*, which determines the path any agent will choose to get to the other side of the hallway. To be more precise, it determines only the next step an agent will take and not the whole path. It relies heavily on the two functions *xValuesLogic.m* to deal with other agents and *xWallLogic.m* to deal with agents representing the wall or static obstacles. At first, the functioning of *xValuesLogic.m* will be explained and afterwards the functioning of *xWallLogic*.

5.5.2 How to get β_{Links} and β_{Rechts} ?

For our model, it is crucial to determine where an agent shouldn't go. The function *getBeta.m* returns the angles which describe the interval leading to a collision. A

Figure 3: The graph shows the angles and variables used to get β_{Links} and β_{Rechts} . α_X is the angle between the two agents with respect to the y -axis. This depiction was engineered to work also for agents walking the other way.

graphical depiction of the situation is given in figure 3. The equations (2) to (4) were used to get β_{Links} and β_{Rechts} . They had to be converted into the angles given with respect to φ , $\beta_{\varphi, \text{left}}$ and $\beta_{\varphi, \text{right}}$ as shown in equations (5) to (6).

$$\gamma = \arccos\left(\frac{r_S}{d}\right), \quad \alpha = \arctan\left(\frac{\Delta y}{\Delta x}\right) \quad (2)$$

$$\beta_{\text{Links}} = \gamma + \alpha - \frac{\pi}{2} \quad (3)$$

$$\beta_{\text{Rechts}} = +\alpha + \frac{\pi}{2} - \gamma \quad (4)$$

$$\beta_{\varphi, \text{left}} = \frac{\pi}{2} - \beta_{\text{Rechts}} = \pi - (\gamma + \alpha) \quad (5)$$

$$\beta_{\varphi, \text{right}} = \frac{\pi}{2} - \beta_{\text{Rechts}} = \gamma - \alpha \quad (6)$$

This works between agents as well as between agents and the wall agents. Care was taken to engineer a calculation that allows for it to be used for agents walking in both directions.

5.5.3 xValuesLogic.m

xValuesLogic.m distinguishes three different cases.

- For two crossing agents or if the agent in front of the agent in question is slower, we used equation (7) to get x'_{out} . It was also used for two not moving agents, setting Δv equal to an arbitrary value given in **STANDOFF**. This was a quick way to resolve standoffs, although this would eventually turn out to be in its actual form an Achilles heel of the model.

$$x'_{\text{out}} = \frac{1}{(|x - \alpha_X|) \left(\frac{-\Delta v}{a} \right)} = (|x - \alpha_X|) \left(\frac{\Delta v}{a} \right), \Delta v < 0 \quad (7)$$

All values which correspond to a collision course in $x_y \text{out}'$ are set to zero. This also deals with the singularity of equation (7) as it is set to zero. This done using the β -angles shown before. Afterwards, x'_{out} is normalized and modified further using equation (8).

$$x_{\text{out}} = x'_{\text{out}} \cdot \frac{b}{\max(x'_{\text{out}})} \cdot \left(\frac{r_S}{d} \right)^c \quad (8)$$

The variables a (called **SLOPEFACTOR**), b (**HEIGHT**) and c (**REPULSIONAGENT**) have to be chosen in a way that the simulation runs smoothly. The term $\frac{b}{\max(x'_{\text{out}})}$ normalized the function to a maximum value b while the term $\left(\frac{r_S}{d} \right)^c$ controls that the repulsive influence gets stronger the closer the two agents get. c is usually chosen to be larger than 1.

For two agents walking in the same direction, the function given in equation 8 is additionally multiplied with the difference in speed $|\delta v|$ in a try to make them avoid standing agents more resolute as it that case $|\delta v|$ would be rather big.

If the x_{out} given in equation (8) would be returned, the agent in question would aim to miss the other agent exactly. We thought that this would be too close as in reality, one also leaves a bit of space if possible between each other. Therefore we introduced an offset given as **WALLANGLEOFFSET** which gives the angle additionally to the β angles for which an agent should aim to. To account for this, x_{out} is modified with a linear interpolation between the values at $\beta + \text{WALLANGLEOFFSET}$ and β (which was set to zero before).

- If the agent in front of the agent in question is faster, a gaussian curve was used with the mean α_X and standard deviation rS/d . It is then modified further with Δv and HEIGHT to make it a weak influence.
- For two agents moving with the same speed, the influence is set two zero by returning a vector of zeros.

5.5.4 xWallLogic.m

To avoid hitting the wall, we used a very simple approach. Every angle corresponding to a collision course is set to a negative value accoring to equation (9).

$$x_{\text{Out}} = x \cdot \frac{a}{d - rS} \quad (9)$$

As before for agents, an offset is introduced so the agent in question doesn't just try to avoid the wall-agent but also to leave some buffer space. The offset is also given in WALLANGLEOFFSET, a can be accessed with the constant variable WALLFACTOR. a has to be set negative as otherwise the wall would have an attractive force. To set a good value for this factor a is quite delicate because if it is too low agents will be stuck in the wall while if it too high they will never approach the wall even slightly.

5.5.5 Calculating functions in x and transforming them into a polar axis in φ

Figure 4: Graphical depiction of the function given in equation (7). In the graphic on the left, the horizontal axis is given in x while in the right graphic the horizontal axis is given in φ .

As the functions given above are given in x but the direction to go on is determined in polar values, it needs to be transformed into a φ axis. This is done using a vector for x ranging $\pm \text{XSCOPE}$ with a step of XRES . Applying the arcustangent on it yields

the axis in angular values (φ). The transforming is done simply by using the φ axis instead of the x axis. This is shown in the two figures 4 and 5. As those functions are only chosen to show the principle, they were not normalized in height according to the equations mentioned above.

In figure 4, the function (7) is shown graphically in the x as well as φ axis. Figure 5 shows the x_{out} the function *xValuesLogic.m* returns.

Figure 5: Graphical depiction of the return values of the function *xValuesLogic.m*. In the graphic on the left, the horizontal axis is given in x while in the right graphic the horizontal axis is given in φ . α_X was set to 0 corresponding to an other agent directly ahead, β was set to ± 0.3 with an offset of 0.25.

5.5.6 Graphical example

This subchapter shall give a visual example of how the logic functions work. Lets consider the situation given in figure 6.

Figure 6: Exemplary case used to demonstrate the working principle of the logic functions.

The blue agent moving up in figure 6 only sees the influence of the wall. What the

blue agent "sees" is given in figure 7. The influence of the wall causes the overall function to decrease for all φ corresponding to a collision course. The offset causes the overall function to have its maximum α at a positive φ . This causes the agent to walk in the direction of α .

Figure 7: Output of all logic functions combined for the blue agent in figure 6. Visible is the effect of wall agents on the blue agent as negative values on the left side.

The green agent moving up sees only the influence of the black agent who is moving down. The effect of that is given in figure 8. The underlying gaussian function can be seen as well as the addition of a modified version of figure 5, left. The agent will move slightly to the left to avoid hitting the black agent.

Figure 8: Output of all logic functions combined for the green agent in figure 6. Visible is the effect of the oncoming black agent as a superposition on the underlying gaussian curve.

The black agent moving down sees the oncoming green and red agent going up. The effect of them is given in figure 9. The superposition of two functions onto the

underlying gaussian can be seen by the discontinuities. The effect of the green agent is stronger as it is nearer to the black agent than the red agent which causes the black agent to go left (looking top-down) in order to avoid hitting the green agent. This shows the dependency of the strength of an agent of the distance.

Figure 9: Output of all logic functions combined for the black agent in figure 6. Visible is the effect of the oncoming green and red agents as superpositions on the underlying gaussian curve. The black agent will move left (from his point of view) to avoid hitting the closer green agent.

5.6 Iteration

5.6.1 General considerations

One iteration step is carried out using the function *Iteration.m*. For it to work properly, the array of all agents and all wall agents has to be passed to it. All other inputs as well as all output variables are introduced for evaluation of the model and are per se not necessary for the iteration. It deals with three main tasks, the propagation of the simulation in time, the collision detection and the destruction of an agent after reaching its goal.

The spawning of new agents is treated in the function *Spawn.m*. Both functions are called from the *simulation.m* which controls the simulation and stores all the data.

5.6.2 Iteration step and collision detection

This function takes four input arrays, although only two are critical for the success of the iteration. Those two are the arrays for all dynamic and static agents (equals wall agents). The output consists of the number of agents which disappeared during the iteration step, the distance covered by the disappeared agents as well as the time the disappeared agents had spent in the simulations.

At first, an index array is calculated with the indices of the dynamic agents in the given array of agents sorted according to their priority. This is done using the functions *getPriorityArray.m* and *getSortedPriorityArray.m*. Then a loop over the index array is carried out.

For every agent, the desired direction is calculated using the function *logicFunction.m* explained above. Using the angle obtained by the call of *logicFunction.m* and the speed given as the agent property, the new x - and y -coordinates-to-be are determined. The path to it is then split in several substeps with the number of divisions given in the constant `PRECISIONCOLLISION`. In addition, the place where the agents stands is also included in case the agent cannot move at all.

For each of these positions, the distance to all other agents minus the radii is calculated yielding a distance matrix. This is done over all agents, dynamic as well as static. The last position for each other agent is left -1 as a sentinel. The distance matrix is then sorted using the matlab command *sort* which leaves the most negative value for each column in the first row. The position of the first negative minimal distance indicates a collision. This position minus 1 will then be the distance the agent in question walks.

In very rare cases, all positions in the first row of the sorted distance matrix are negative. This has the very nasty significance of an agent that could not even stand at its actual position. We reckon this has to do with some small numerical errors, as it occurs very rarely. To leave the agent at its actual position will now only result in a complete freeze of two agents. It is certainly not a nice solution, but in these cases we simply deleted the faulty agent by setting its priority to 0 and reset its distance and time properties to enable the simulation to keep on running.

5.6.3 Destruction of agents

If an agent reaches his goal, namely the other side, it is automatically deleted inside *Iteration.m*. This is simply done by setting the priority of the agent to 0. The attributes time and distance are read out before resetting and handed back to the calling function for later evaluation. After a deletion, the priority array giving all the indices of active agents is recalculated in order to avoid any influence of the deleted agent on other agents as the iteration step proceeds through the residual agents in the loop over all agents.

5.6.4 Spawning new agents

Spawning of one new agents is done by the function *spawn.m*. Every call of *spawn.m* spawns a new agent, whether the function is called at all is handled an instance

higher in the simulation class. After each iteration step, namely by calling *Iteration.m*, the class simulation determines whether a new agent is spawned or not.

There are two constants determining the amount of agents spawned over a long period called **DENSITYUP** and **DENSITYDOWN**. They correspond to a density of people or, in other words, the number of people per second that should appear. As the names suggest, one is used for the number of agents walking upwards while the other is used for the number of agents walking downwards. This information is then passed down to the function *spawn.m* in the variable *position* which can only take the values 1 or -1 . Using our implementation, maximally one agent is spawned per iteration per side according to the following equation with the according density ρ and the time step length Δt .

$$p(\text{spawn}) = \begin{cases} \Delta t \cdot \rho & \Delta t \cdot \rho \leq 1 \\ 1 & \Delta t \cdot \rho > 1 \end{cases} \quad (10)$$

For sufficiently small values of Δt and ρ , it can be in good approximation assumed that only one agent is spawned per time step. The probability of spawning two agents would go with p^2 which is small for the values we have chosen. Otherwise one would have to implement an additional condition which would determine at first how many agents are to be spawned with the probability for spawning n agents going in principle with p^n .

To spawn an agent, the first agent position in the array of agents with a priority of 0 is taken. The radius is generated using a normal distribution (*randn* in matlab) with a mean of **MEANRADIUS** and a standard deviation of **STDRADIUS**. The maximal deviation possible was set to be three times the standard deviation. Should the generated radius be out of bounds, the radius generating procedure was simply repeated. A starting position in x -direction is then generated with an uniform random distribution over all possible starting values. A collision detection is then carried out to see whether the chosen position is possible without spawning onto another agent. If it fails, this procedure is repeated **REP** times, a constant defined at the beginning. The y -position is given by the dimension of the field while the velocity is determined using a normal distribution in the same way as before for the radius with the mean given by **MEANSPEED** and the standard deviation given by **STDSPEED**.

It is possible to implement other spawn sequences than the one used for this model. If one wishes to get specific agents with certain properties, they could also be spawned directly from the simulation.

5.7 Readout of informations of after a simulation

To evaluate how the model has worked, both a graphical and a mathematical output is given. As a graphical check one can take a look at the last situation which is saved as a png. This gives immediate information about whether the agents got caught in a jam or not.

For further and more precise analysis, several variables listed below are stored which can be used to monitor several aspects like the overall efficiency of the model. In the list below, the variables are stated in the way they can be called after a simulation.

- **sim.loops**: Gives back the number of iterated loops.
- **sim.evaluateDistance**: $(1 \times (\# \text{ of arrived agents}))$ -matrix containing the distances of all agents which have finished their way across the hallway.
- **sim.evaluateTime**: $(1 \times (\# \text{ of arrived agents}))$ -matrix containing the spent time in the simulation of all agents which successfully crossed the hallway.
- **sim.spawned**: $(2 \times \text{loops})$ -Matrix containing the number of spawned agents at the top (column 1) and bottom (column 2) of the hallway.
- **sim.result**: $(2 \times \text{loops})$ -Matrix containing the number of deleted agents at the top (column 1) and bottom (column 2) of the hallway.
- **sim.additionalresult**: $(2 \times \text{loops})$ -Matrix containing the total distance walked by all agents during each iteration step (column 1) and the total number of agents in the system (column 2).

5.8 Defining all constants

The file *defineConstants.m* contains all the constants that are used somewhere in the simulation. They can be grouped into several categories which are listed below, only the most important and most frequently changed constants are listed explicitly.

- The first section containing **XSCOPE** and **XRES** define the extent of the numerical approximations. An acceptable compromise between numerical resolution and runtime has to be chosen.
- In the second section, the model parameters can be set. They were explained in the subchapters about the logical functions and the spawning.
- The third section is used to define the field in which the agents will walk.

- In the fourth and last section, general parameters concerning the simulation can be set. They include the time increment **DELTAT** and the number of loops **LOOPS** for the iteration process. The seed for the random number generator can be set with **SEED**.

The seed for the random number generator is important to get random numbers but reproducible results.

Please note that early simulations may have a slightly different ordering of the constant variables in their logfiles.

6 Performed simulations

Listed below are the carried out simulations with their parameters. For each series of simulations, a brief explanation is given to state the questions which will be looked at with the actual simulation series.

All parameters can be found in the corresponding logfiles. Usually only one parameter was varied while all others were kept constant. We chose a mean radius for the agents of 0.25 meters with a standard deviation of 0.03 meters. A mean velocity of 1.5 meters per second was chosen with a rather large standard deviation of 0.25 meters per second.

It should be noted that we usually used high people flux densities since we wanted to test the model under stress conditions. Therefore we expected a considerable amount of failure in the examined situations.

6.1 Influence of different pedestrian flux densities

To check the influence of different densities on our model, we ran the simulation with the density combinations 0.4/0.4, 0.4/0.6, 0.4/0.8, 0.4/1.0, 0.6/0.6, 0.6/0.8, 0.6/1.0, 0.8/0.8, 0.8/1.0 and 1.0/1.0. The first number represents the value chosen for `DENSITYDOWN`, the second for `DENSITYUP`. We didn't run the inverted combinations due to the situations symmetry. The simulations were repeated with three different seeds each, 51, 71 and 91. A high value for `DISPERSIONFACTOR` of 1.0 was chosen which corresponds to people having a strong tendency to try to overtake slow agents.

6.2 Influence of overtaking or lane formation on the success of the model

It soon became clear to us that the parameter `DISPERSIONFACTOR` would be absolutely crucial if one wants to force the model to succeed. A negative value encourages the agents to form lanes while a positive value encourages them to try finding their own way. In order to investigate this property, specially with the dilemma of personal vs. group success in mind, we ran a simulation series where we incremented the `DISPERSIONFACTOR` from -0.2 to 1 each time by 0.1. A high density flux of 1 person per second on both sides was used to test the model in a stress situation. This was done for three different seeds each, 51, 151 and 351.

6.3 Influence of the radius of sight of an agent

The constant variable `INFLUENCESPHERE` determines the radius of the semi-circle in which the agent considers other agents around him. With flux densities of 1.0 each and a `DISPERSIONFACTOR` of 0.7, the `INFLUENCESPHERE` was tested using the values 1.5, 2.0, 2.5 and 3.0 (in meters). This was done for three seeds each, 51, 77 and 151.

6.4 Influence of the hallway width on the success of the simulation

To account for the influence of the width of the hallway on the success of the simulation, we did a simulation series with different widths. The tested widths were 2.2, 2.5, 2.8, 3 and 3.5 meters. A high density flux of 1 person per second on both sides was used with a `DISPERSIONFACTOR` of 0.75 corresponding to a high number of overtaking attempts. The simulations were repeated with the seeds 51, 77 and 151 each.

6.5 Simulating measurements of the main station Zurich

Saturday, Nov 17th, we did some quick measurements right at Zurich main station to have some data we could try to compare. Two measurements were taken, only some minutes lay between these, that was when we measured the length and breadth of our corridor. The measurements were:

1. The "boring" measurement: During 2 minutes, 14 pedestrians headed towards tracks 3-18, and 20 pedestrians directed towards tram station "Bahnhofsquai". No problems at all, very fluently.
2. The "crowded" measurement: During 2 minutes, 41 pedestrians headed towards tracks 3-18, and 33 pedestrians directed towards tram station "Bahnhofsquai". People got stuck, ran into each other, had to walk stop-and-go-like for some moments.

7 Simulation Results and Discussion

7.1 Goals

First, let's have a look at what our goals were. We planned to have a look at the pedestrian flux, how it can be improved and jammings be avoided. We furthermore wanted to have a closer look to what happens during rush-hours and in a situation when much more people are moving in one direction than in the other.

On the agent-based side of our model, we wanted to analyze the influence of aggressive fast people in a rush, slowly moving obstacles (eg. mothers with baby buggies) and the influence of drunkard (more or less randomized walking) on the pedestrian flux.

If everything went well, we also wanted to implement a static obstacle and see what happens. As a reminder before the discussion of the results, our fundamental research questions were:

- How does the simulation behave in the following situations: rush hour, with obstacle, with very slow/fast agents, random path agent (drunkard)? Does it run smoothly or will there be jams?
- How will our implementation of a rudimentary kind of "thinking ahead" affect the simulation? Will it work good or bad? Can we compare it to other implementations?
- Are there any group dynamics evolving as lane or group formation?

7.2 General achievements

As soon as we started programming we realized there was a major point of importance about this work we all were aware of, but had forgot to put it in the project proposal. We all did not want to start with an already known program or existing algorithms, but build something "new". So we started off creating our logic function that would allow the agents to avoid crashing into other agents and not working with repulsive forces as for example Helbing (Quelle angeben, ist das älteste Paper) did. Quite proudly, we can now say we managed to do this. Our idea of the agents "thinking ahead" by consulting where other agents are and not just being pushed around by repulsive forces worked.

We now are able to play with lots of input variables, the most important being number of agents entering the corridor per time and the agents' characteristics as size, speed and lots more.

A nice thing we built but did not originally plan to is that we planned to and did research on the situation as explained earlier in the long, narrow corridor in Zurich

mainstation. But in our simulation, one can also change dimensions as length and shape of the walls easily.

We therefore decided to make first of all sure that the model works and what are its operating parameters. This meant that we had to drop a lot of our former goals because we did not want to carry on with a faulty model. Therefore we have included some results that were not included in our first questions we set out to answer in the beginning.

On the downside of this, we dropped the investigation into the behaviour of the pedestrian flux when exposed to aggressive, slow or random people. Even though these situations were not simulated, the functionality to introduce them without much work was implemented into the model as they were considered when we built our model.

MATLAB HS2012 - Research Plan

Version info: the submitted and approved version, 2012-10-24 17h

- **Group Name:** Mayara
- **Group participants names:** Moser Manuel (Mathematics BSc, 3rd Sem), Suter Yannick (Chemistry BSc, 5th Sem), Theiler Raffael (Informatics BSc, 3rd Sem)
- **Project Title:** Pedestrian dynamics in long, narrow hallways

General Introduction

Annoyed by people rushing through the small corridor left in Zurich main station hall (the path between burger king and groups meeting point) during the Oktoberfest, market days, concerts and other occasions, we decided to have a look at pedestrian dynamics in hallways which are mostly crowded and narrow (3-4 meters in breadth) compared to normal days when the hall is empty, and where people walk through in opposite directions all the time. We want to have a look at how the pedestrian flux can be improved and how the walk-through time behaves during rush-hours, but also in the case of much more persons moving in one direction than in the other. Also, we want to have a look at the influences of aggressive, fast people in a rush, slowly moving obstacles like mothers with baby buggies and some drunkards, and try to figure out how to avoid jammings. Maybe we'll also implement a static obstacle to observe what happens. The simulation of problems like this will also help understand the phenomena of group dynamics which usually control and resolve such problems in real life.

The Model

We want to do an agent-based simulation of people moving through a long corridor (dimensions will be proportional to those encountered in our object, the Zurich main station). The people will primary want to move forwards at different speeds but also be able to move diagonally or even sideways if needed. A nice thing will be to try implementing agents being able to see some fields/meters ahead whether their path (assumed straight as long as possible) is free or not, and if they're about to crash into someone, try to avoid them. Independent variables in our model are the amount

of people per time arriving, the corridor and its obstacles and the characteristics of the agents like walking speed and aggressiveness. Dependent variables will be the amount of people leaving, which should in the end determine whether the people will be stuck or if they can get through. Should the amount of people leaving be smaller than those arriving (per time unit), one can expect a blockage. As a reference, we will use a simulation of a corridor without any obstacles and only few people. Then the collective success or failure of an other situation can be compared to this.

Fundamental Questions

- We try to simulate the pedestrian flux in the following different situations: Rush hour (danger of jamming), with an static obstacle, with aggressive/very fast or slow agents, random path agent (drunkard). Will the pedestrian flux run smoothly or will they block each other and be stuck?
- Will the implementation of a rudimentary kind of thinking/looking ahead help to avoid blockages? If possible, we may determine the limits for which the goal of passing is achieved with and without this implementation and compare them.
- Will there be group dynamics or similar behaviors of agents if they're only programmed to walk to the other side, each on his own?

Expected Results

We think that there will be lots of walking around left/right while trying to avoid other agents, and with rising amount of agents there will be more jams, this seems obvious. We think that in our simulation we'll have to deal with massive jams because the agents are not communicating with each other in any way. Implementation of "looking ahead" will probably improve the people flux but only to a limited range. Obstacles will also lead to more jams, whilst the drunkard simulation will for the amusement of our group.

Research Methods

For our project, an agent-based model is the most satisfying because there we can really implement different speeds and directions. A disadvantage will be the complicated collision handling.

Other

For the measurements of the corridor, we'll go to the main station and measure it one afternoon when it's not fully crowded. We also could count the rate of incoming and leaving people during a rather relaxed afternoon and a crowded rush-hour.
